Introduction

Fair division is a problem with roots in the Bible and in Greek mythology. When Abraham and Lot must divide the land of Canaan fairly among themselves, one divides the land into two parts (which they perceive to be equally valuable), and the other chooses their favorite piece. This problem has proven to be useful in practice. It has been used for international dispute resolution (Brams 2019), distribution of food for food banks, and estate divisions (Aleksandrov et al. 2015; Mertzanidis, Psomas, and Verma 2024; Caragiannis et al. 2019). This was formalized by (Steinhaus 1948) for both divisible continuous and indivisible discrete goods. Since then, several promising results have been published in both settings, with the existence of a bounded-time envy-free cake cutting procedure being resolved by (Aziz and Mackenzie 2017). However, the fair allocation of a finite set of indivisible goods to individuals "fairly" remains a fundamental open question within computer science and economics. Indeed, many interpretations of fairness exist. In this paper, we survey some common notions of fairness, their computability, and open questions within the field of Fair Division. We also present a small result connecting two notions of fairness (MNW and EOX).

Preliminaries

Let html.frame be a set of agents with html.frame and html.frame be a set of goods with html.frame. Each agent html.frame possesses a valuation function html.frame, representing their value of each bundle of goods within html.frame. It is assumed that for each agent html.frame that html.frame. For simplicity, we write html.frame as html.frame for individual items html.frame. The valuation function is usually taken to be additive, meaning that an agent's value of a html.frame is equal to the sum of the agent's values of the individual goods. Formally, html.frame. For more general contexts, the valuation function is taken as monotone, i.e., that html.frame for all html.frame. In this survey, we focus on the additive context, however several of the results hold for monotone valuations as well.

An allocation html.frame is a partition html.frame into html.frame disjoint sets and assign each partition to an agent html.frame. The subset of html.frame assigned to agent

html.frame (called html.frame's bundle) is denoted html.frame, and each agent html.frame's valuation of their own bundle is html.frame's "utility". The goal of fair division is to take a tuple html.frame and to compute a "fair" allocation efficiently. To this end, there are several notions of fairness. Computing fair allocations efficiently is not always known to be possible, or is hard, so the valuation functions are restricted. We primarily focus on two settings, that of identical valuations where html.frame, and binary valuations where html.frame. In these contexts, several notions become easier to compute.

Envy

Arguably, the gold standard of fair division is envy freeness (EF), where no agent would like another's bundle more than their own. Formally, html.frame. If this is not the case, (i.e. html.frame), html.frame is said to "envy" "j". It is clear that for discrete goods, this does not always exist, as seen in the following counterexample:

Proof: Take two agents 1 and 2 and one positively valued good. Without loss of generality, allocate the good to agent 1. Agent 2 envies agent 1, as html.frame and html.frame.

Worse still, computing if an arbitrary instance admits an EF allocation is NP-complete (Lipton et al. 2004).

Thus, when allocating a finite set of goods, EF is relaxed to envy-freeness up to X (EFX) by allowing the removal of an arbitrary good from another agent's bundle such that html.frame for all html.frame.

For two agents, EFX can be computed using a variation of the "cut-and-choose" procedure. The first agent divides html.frame into two bundles, html.frame and html.frame such that they value each of them as near to html.frame as possible. Then, the second agents chooses the bundle which gives her higher utility, breaking ties arbitrarily. The second agent clearly does not envy the first, as they received the bundle with the highest valuation in their eyes. If the first agent prefers the bundle they received, we are done. Otherwise, the first agent cannot envy the second after the removal of a good, as otherwise this bring the valuation of the bundles closer to html.frame, which would contradict that the first agent selected as near to html.frame as they could initially. For three agents, (Chaudhury, Garg, and Mehlhorn 2024) showed that EFX can be computed as well in pseudo-polynomial time. (Akrami et al. 2022) later gave a simpler algorithm for this using casework to iteratively improve the allocation.

Thus, we come to our first open question.

Open Problem 0.1: Do EFX allocations always exist? If so, can they be computed efficiently?

The leximin solution is one which maximizes the minimum utility, then maximizing the second least utility, and so on. The leximin++ is the leximin solution, which, after maximizing the value of the bundle with minimum utility, maximizes size of the bundle. Then, maximizes the size of the second least agent's utility subject to maximizing the size of the second bundle and so on.

For identical additive valuations, an EFX allocation can be computed by taking the leximin+ maximal allocation. (Plaut and Roughgarden 2020)

Proof: For contradiction, let html.frame be a leximin++ allocation which is not EFX html.frame for html.frame. This means that there is a pair of agents with html.frame, where html.frame for some html.frame. This means that the minimum utility of the bundle can be increased by giving that good html.frame to html.frame, contradicting that html.frame is a leximin++ allocation.

Although computing EFX for general additive valuations remains an open problem, several relaxations of EFX have been proposed which are easier to compute.

One natural easy-to-compute notion relaxation of EFX is EF1. Rather than allowing the removal of an arbitrary good, this is relaxed so that there must exist a good which can each be removed in order to resolve envy. In other words, html.frame for a good html.frame. This notion was first formally defined by (Budish 2011). Note that this is equivalent to removing the good which html.frame values the most in html.frame's bundle to enforce envy-freeness html.frame, with html.frame. For general valuations, EF1 can be computed efficiently using simple polynomial time algorithms.

One such well-known algorithm is the round robin algorithm, presented below: Informally, the algorithm iterate through agents in a fixed order, giving them their most valued good at each step (breaking ties arbitrarily) until no goods remain.

Round-Robin

Input: html.frame

Output: An EF1 allocation X

- 1 html.frame
- 2 html.frame
- 3 i := 1
- 4 **while** |P| > 0
- 5 | html.frame # Give html.frame their favorite good.
- 6 html.frame
- 7 html.frame

(Caragiannis et al. 2019) Round-Robin produces an EF1 allocation

Proof: Take two agents html.frame and html.frame. After the execution of fixed-order round-robin. First, we note that an agent html.frame cannot envy only value another agent html.frame with (html.frame). This is trivial for html.frame, so let us take html.frame. Here, in each iteration of the loop, html.frame chooses their favorite good after html.frame. Thus, html.frame believes they received a weakly more valuable good than html.frame. Thus, we get html.frame

Note that in each iteration of the loop, for html.frame, html.frame receives weakly more than what html.frame will receive in the following iteration of the loop according to html.frame. We then only need to consider the first iteration of the loop, as envy cannot come from later in the execution of the algorithm. Since html.frame may value html.frame for html.frame by the item allocated in the first iteration of the loop, then the removal of the item will remove html.frame's envy of html.frame. Thus, the allocation is EF1.

Another common algorithm for computing an EF1 is Envy-Cycle Elimination. Define the envy-graph html.frame, with html.frame and a directed edge between agents, html.frame iff html.frame. The algorithm works as follows. Find an arbitrary unenvied agent html.frame and give them their most valued good. If no such agent exists, then there must be a cycle html.frame where html.frame envies html.frame (as otherwise there would have to exist a sink, as it would be a DAG). To remove or "eliminate" this cycle (then for agent html.frame, give them the bundle of agent html.frame). Until an unenvied agent is found, repeatedly remove directed cycles. Then, give the agent their most favorite unallocated good.

Envy-Cycle Elimination

html.frame

html.frame

10

11

Input: html.frame Output: An EF1 and html.frame-EFX allocation html.frame html.frame for html.frame html.frame for html.frame while html.frame unenvied agent # Perform envy-cycle elimination Find an envy cycle html.frame html.frame let html.frame be an unenvied agent # Find an unenvied agent html.frame let html.frame # Give html.frame their favorite good.

Proof: Before the algorithm begins, the allocation is trivially EF (and EFX), as no good has been allocated and thus all bundles are valued at 0 by all agents. In each iteration of the loop, the algorithm allocates goods only to unenvied agents This implies that an agent may only envy another by a single good. This then implies that the algorithm is EF1 after each iteration of the loop, as the removal of a good html.frame causing envy for any html.frame who envies html.frame will resolve envy.

html.frame-EFX

Another relation of EFX is html.frame-EFX, where html.frame for html.frame.

Open Problem 0.2: What is the greatest html.frame for which an html.frame-EFX allocation exists?

It is important to note that if the best possible html.frame, then EFX allocations can always exist, but otherwise, this question becomes meaningful as well.

(Plaut and Roughgarden 2020) first attempt to compute approximate-EFX allocations by slightly modifying the Envy-Cycle elimination algorithm to compute html.frame-EFX. (Chan et al. 2019) show that Envy-Cycle Elimination by itself can compute a html.frame-EFX allocation, if ties are broken between unenvied agents in favor of those with empty bundles.

(Chan et al. 2019) Envy-Cycle Elimination produces an html.frame-EFX allocation

Proof: Take two distinct agents, html.frame. Assume that html.frame for all html.frame. This statement holds trivially for html.frame, so assume that html.frame.

Let html.frame be the good last allocated to html.frame Since ties are broken in favor of empty bundles when picking an agent to allocate to, html.frame, as otherwise html.frame would have been allocated to html.frame rather than html.frame.

Because html.frame, there must have been a round before html.frame during which html.frame was able to pick an item. Although html.frame might be swapped with other agents' bundles, html.frame is non-decreasing. Therefore html.frame.

Additionally, by the design of the algorithm, html.frame. Together, these imply that

html.frame

Thus, the allocation is html.frame-EFX.

html.frame

(Amanatidis, Markakis, and Ntokos 2020) improve this to a html.frame-EFX allocation. Most recently, (Amanatidis, Filos-Ratsikas, and Sgouritsa 2024) compute a html.frame-EFX allocation for general valuations.

Pareto Optimality

Take two allocations html.frame and html.frame. html.frame is said to "Pareto Dominate" html.frame iff html.frame for all html.frame, and for at least one agent, html.frame. This induces a partial ordering on the set of all feasible allocations. The maximal element(s) are said to be "Pareto Optimal".

(Plaut and Roughgarden 2020) PO and EFX do not coincide for all fair division instances if zero marginal utility is allowed.

Proof:

	a	b	С
agent html.frame	html.frame	html.frame	html.frame
agent html.frame	html.frame	html.frame	html.frame

html.frame and html.frame for a PO allocation, html.frame must be given to agent html.frame. Similarly, html.frame must be allocated to agent html.frame as html.frame and html.frame.

Assume without loss of generality html.frame is allocated to agent html.frame. Then html.frame.

Like Pareto dominating allocations, Lorenz dominating allocations induce a partial ordering over the set of allocations. Here, take two vectors of utilities which have been sorted html.frame and html.frame. html.frame is said to "Lorenz dominate" B iff for every html.frame (Babaioff, Ezra, and Feige 2021).

MMS

A Maximin-Share Fair allocation is one maximizing the "worst-off" agent according to each html.frame. In other words, all agents html.frame, html.frame.

Unfortunately MMS may not always exist, (Kurokawa, Procaccia, and Wang 2016), although it exists with high probability in general. Additionally, MMS is hard to compute (Woeginger 1997). Thus, several recent papers try to approximate it so that html.frame, with html.frame. This is known as an html.frame-MMS allocation.

Oe common technique for producing html.frame-MMS allocations is known as the bag-filling algorithm. First, the MMS values of all agents are normalized such that html.frame for all agents html.frame. Maintain a "bag", and keep adding arbitrary goods until an agent html.frame values the bag at least html.frame, breaking ties arbitrarily. Once such an agent is found, add all the goods in the bag to html.frame and remove them from html.frame. When a single agent remains, give her the remaining unallocated goods.

Bag-Filling

Input: html.frame

Bag-Filling

Output: A html.frame-MMS allocation X

- 1 html.frame
- ² html.frame
- 3 while html.frame such that html.frame
- 4 | html.frame # Give html.frame their favorite good.
- 5 html.frame
- 6 html.frame
- 7 **while** html.frame
- 8 | while html.frame with html.frame
- 9 | html.frame arbitrary html.frame
- 10 html.frame
- 11 Take html.frame where html.frame
- 12 html.frame
- 13 html.frame
- 14 Let html.frame be the remaining agent in html.frame
- 15 html.frame

(Garg, McGlaughlin, and Taki 2019) Removing an agent and removing a single good from a problem instance produces results in a weakly greater MMS value. In other words, html.frame for an arbitrary html.frame.

Proof: Before the removal of the agent and good, html.frame. Suppose w.l.o.g that html.frame, and reallocate all other html.frame to the other agents html.frame. This is clearly an allocation html.frame, denoted by html.frame. Since each agent has weakly greater utility in the new allocation, html.frame.

(Garg, McGlaughlin, and Taki 2019) The bag-filling algorithm produces a html.frame-MMS allocation.

Proof: In each round of the algorithm, the bag is allocated with an agent with value at least html.frame for the bag. Note that the value of the other agents for the given bag is smaller than 1. Since, before the last good is added to the bag, the value of the bag for all agents is smaller than html.frame and greater than html.frame for at least one agent after. Thus, when an agent takes away a bag in some round, the remaining html.frame agents have total value at least html.frame of the remaining bundle. This can be repeated until 1 agent remains, who will then receive their entire MMS value.

html.frame

(Procaccia and Wang 2014) first showed the existence of html.frame-MMS approximation algorithms. (Garg, McGlaughlin, and Taki 2019) present a simple algorithm for computing such allocations by modifying the bag-filling algorithm to use low, medium, and highly

valued goods to compute a html.frame-MMS allocation. Several works attempt to (Garg and Taki 2020) compute html.frame-MMS allocations, achieving up to an- html.frame-MMS allocation (Akrami et al. 2023), but with no improvement on the constant approximation factor. Very recently, (Akrami and Garg 2024) improve this to a html.frame-MMS.

Despite the progress made in computing approximations, the approximation of MMS is incomplete. (Feige, Sapir, and Tauber 2022) showed a counterexample, showing that MMS allocations cannot always be approximated higher than html.frame, even for 3 agents.

Open Problem 0.3: What is the highest possible html.frame for which html.frame-MMS allocations exist?

Open Problem 0.4: Does a stronger approximation bound exist than html.frame?

Maximum Nash Welfare

Maximum Nash Welfare (MNW) is a more "global" notion of welfare. Namely, it considers the utility of each agent rather than agents' value over others'. This first maximizes the number of agents receiving positive utility, then maximizes the geometric mean of utilities. Let html.frame represent the set of all partitions of a set S into k elements. The MNW allocation is given by html.frame.

In the notion of the geometric mean, under identical additive valuations, this is maximized when all agents with positive utilities have valuations which are as similar as possible (after maximizing the agents with positive utilities). This is quite useful, as MNW provides strong guarantees for other notions of fairness.

(Caragiannis et al. 2019) A MNW allocation is PO and EF1

Proof: MNW implies PO, as a Pareto dominating allocation would have a higher product of utilities. It is left to show that MNW html.frame EF1.

Assume for contradiction that MNW html.frame EF1. This implies that there exists html.frame where html.frame.

Proving EF1 is slightly more involved. Assume for contradiction that there exists two agents html.frame and html.frame such that html.frame for every html.frame. We must show that there is another allocation html.frame with Nash Welfare larger than that of html.frame.

Because html.frame envies html.frame, there exists a html.frame. Let html.frame = html.frame for all html.frame. Next, move the html.frame from html.frame's bundle to html.frame's. In other words, html.frame and html.frame.

We must show that html.frame

To begin, we know that html.frame, which implies that

html.frame, since html.frame envies html.frame even after the removal of an item html.frame in html.frame. Therefore.

html.frame

html.frame

which, from the previous inequality, html.frame html.frame

html.frame

(Caragiannis et al. 2019) also showed that a MNW allocation is guaranteed to be html.frame -MMS.

These guarantees however do not extend much further. (Amanatidis et al. 2021a) show that MNW does not give an EFX allocation in general, MNW is NP-hard even for identical additive valuations (Roos and Rothe 2010), although under binary and bi-valued (where html.frame) instances it can be computed in polynomial time (Barman, Krishnamurthy, and Vaish 2018a). For 3-value instances, where html.frame, the problem of computing a MNW allocation is NP-complete (Amanatidis et al. 2021b). Thus, due to its hardness to compute, we seek to guarantee these properties without computing them through MNW.

Open Problem 0.5: Can an EF1 and PO allocation be computed in polynomial time?

As computing MNW allocations is APX-hard, thus prior research has sought to approximate MNW allocations for its desiderata. Can an EF1 and PO allocation be computed in polynomial time? For bounded valuations, (Barman, Krishnamurthy, and Vaish 2018b) develop a polynomial time algorithm, and in pseudo-polynomial time for general valuations.

Open Problem 0.6: What is the best possible html.frame for which html.frame-MNW allocations exist?

EQX

Another notion of fairness based on utilities is EQX. An equitable (EQ) allocation is one in which all agent utilities are roughly the same. html.frame, however like EFX, this clearly does not exist. This motivates a similar relaxation, by allowing the removal of a good html.frame . EQX is well studied in the literature for both goods and for chores, and unlike EFX, is fairly easy to compute.

For identical valuations, EFX coincides with EQX, both of which can be computed efficiently. For strictly positive valuations, an EQX + PO allocation always exists, and an EQ1 + PO allocation can be found in pseudo-polynomial time (Freeman et al. 2019).

(Barman et al. 2024) shows that for all chores or all goods, EQX exists even for monotone allocations, and can be computed in polynomial time, although this is not true for arbitrary valuations (unless P=NP).

html.frame under identical additive valuations.

Proof: Assume for contradiction that MNW does not imply EQX under identical valuations. Start with an MNW allocation html.frame. This means that there is an agent from which html.frame. Otherwise, if html.frame EQX holds trivially.

If html.frame, then it suffices to show that moving a good from html.frame to html.frame will result in a larger geometric mean.

html.frame

html.frame

html frame

By the assumption,

html.frame

and since valuations are additive html.frame, so html.frame. Thus we have derived a contradiction, as html.frame is increased by moving the good html.frame.html.frame

Between EFX and EF1

EFL (Envy-Freeness up to a Less Preferred Good) is meant to be "in-between" EFX and EF1. For agents html.frame and html.frame, rather than allowing the removal of an arbitrary good from html.frame, it only allows the removal of goods html.frame which are less valuable to html.frame than html.frame. In other words html.frame for html.frame and html.frame. This can be computed in polynomial time using envy-cycle elimination.

Randomness

Another line research focuses on randomness in fairness allocations.

EFR

(Farhadi et al. 2021) introduced the notion of envy-freeness up to a random good (EFR), where the expected envy of html.frame towards an agent html.frame can be eliminated. (Farhadi et al. 2021) also show that a html.frame-EFR allocation can be computed in polynomial time. However, such a mechanism cannot be strategyproof and envy free even in expectation (Basteck and Ehlers 2023).

Improving the Maximin Share

GMMS

EFX can be connected to to MMS through the stronger notion of (Groupwise MMS) GMMS.

(Barman et al. 2018) define an allocation as GMMS as if for all subsets of html.frame and their bundle, their allocation is also MMS. html.frame. It is clear that because MMS allocations do not exist, GMMS allocation allocations do not always exist.

PMMS

PMMS is a slightly weaker form of GMMS, in which html.frame. In other words, for all html.frame, html.frame.

A slightly easier notion is html.frame-GMMS, where html.frame. (Barman et al. 2018) show that html.frame-GMMS allocations always exist, and can be computed efficiently. (Amanatidis, Markakis, and Ntokos 2020) show that improved this to a html.frame approximation. The currently highest approximation is to html.frame-(Chaudhury et al. 2021).

A similar line of work has attempted to approximate PMMS, with the highest known approximation as an html.frame 0.781-PMMS allocation (Kurokawa 2017).

Open Problem 0.7: What is the highest html.frame for which html.frame-GMMS allocations exist?

GMMS connects MMS (and its related notions) to EF and its relaxations through the hierarchy:

html.frame

(Barman et al. 2018) GMMS strictly generalizes MMS and PMMS.

Proof: It is trivially true that html.frame and that html.frame, as MMS must hold for all subsets for html.frame for html.frame respectively by the definition of GMMS. For showing that html.frame, we provide the example given by (Barman et al. 2018).

Take an instance with html.frame agents and html.frame goods, where html.frame. This means that html.frame, since some agents must receive nothing. html.frame, and html.frame. For html.frame and all other agents html.frame.

Take an allocation html.frame, with all other agents receiving html.frame. This is both MMS and PMMS, but is not GMMS. html.frame

Other EFX Notions

Epistemic EFX

(Aziz et al. 2018) proposed the notion of Epistemic Envy-Freeness where for each agent html.frame, the allocation can be made envy-free for html.frame by redistributing html.frame among html.frame. (Caragiannis et al. 2023) propose the slightly weaker notion of Epistemic EFX, defined similarly, but only requiring that the allocation can be made envy-free up to html.frame for html.frame. (Akrami and Rathi 2024) recently showed that EEFX allocations always exist and can be computed in polynomial time.

Open Problem 0.8: Do Epistemic Envy-Free allocations exist in general?

Charity

Although the existence of EX allocations is open, it always exists for a subset of goods. For example, trivially, the remoal of all goods yields and EFX allocation. The meaningful form of this is the idea of "charity", where a set of goods html.frame remain unallocated (i.e. "donated" to charity), and no agent should envy charity. (Chaudhury et al. 2021) give a polynomial time algorithm which donates at most html.frame goods to charity. (Berger et al. 2021) improve this to donating html.frame goods, and give an algorithm which donates only 1 good in the case of 4 agents.

Open Problem 0.9: Does EFX exist while donating a sublinear number of goods to charity?

Note that if an EFX allocations with 0 goods may be donated to charity exists, this is simply an EFX allocation.

(Akrami, Rezvan, and Seddighin 2022) propose a similar notion called EFkX, in which the removal of 2 goods from another agents' bundle rather than just one (i.e. EF1X is the same as EFX). They show the existence of EF2X allocations for restricted additive valuations (where html.frame). note that an EFX allocation with charity can be turned into an EF2X allocation by giving the html.frame goods to html.frame unique agents.

Different Setting

Online Fair Division

While in the traditional model of fair division, items are assumed to be standard, agents and/or goods may arrive in an online manner. (Aleksandrov and Walsh 2020) survey online fair division in depth. Here, either agents, goods,or both arrive online at times html.frame. One approach to online fairness mechanisms is to asymptotically allocate goods such that envy the envy-per-good html.frame tends to 0, where html.frame is the maximum envy

one agent has. (Benade et al. 2018) show that randomly allocating goods removes the expected envy. More interestingly, it is impossible to do better than such a mechanism, which is optimal up to a logarithmic factor. Online fair division however is not unilaterally easy to compute. (Aleksandrov and Walsh 2019) show that an ex-ante envy free (i.e. envy-free in expectation) and PO allocation may not always exist.

(Aleksandrov and Walsh 2019) A simultaneously ex-ante envy-free and PO allocation does not always exist.

Proof:

Agent	html.frame	html.frame
1	1	2
2	2	1

By the definition of ex-ante envy-freeness, each agent must have equal probability of receiving each item (i.e. html.frame), however to ensure ex-ante Pareto optimality, each agent must only be given their favorite item.

html.frame

Chores and Mixed Manna

When all goods are chores, i.e. html.frame, the problem of fair division becomes much more difficult, and leads to several open problems. EFX for chores does not exist, and indeed is NP-complete to compute (Christoforidis and Santorinaios 2024). Should such an allocation exist, it is mutually exclusive from PO (Barman, Narayan, and Verma 2023). It also cannot have a finite approximation. Still, under the restricted context of bi-valued and binary valuations, EF1 and PO allocations exist (Ebadian, Peters, and Shah 2021; Barman, Narayan, and Verma 2023).

The division of goods html.frame with arbitrary valuations, where html.frame have shown several barriers for computation. For EQX allocations, (Barman et al. 2024) showed that EQX allocations are not guaranteed to exist, even under additive normalized valuations, and that determining if such an allocation exists is strongly NP-hard.

Incentives

Consider a setting with strategic agents. Here, an agent may misreport their valuations of goods in order to receive a better allocation. A *strategyproof* allocation is one in which such misreporting is not beneficial for such an agent.

Strategyproof mechanisms may not always exist while fulfilling the desiderata. (Caragiannis et al. 2009) show that in the context of strategic agents, an EFX allocation may not exist. (Amanatidis, Birmpas, and Markakis 2016) showed that no truthful mechanism could output an html.frame-MMS allocation for html.frame. Indeed, overall truthful mechanisms (Amanatidis et al. 2017) are incompatible allocations for general valuations.

For some restricted contexts, however, this can be done. Namely for binary valuations, computing an MNW and Lorenz-dominating allocation (and thus trivially a PO and EF1)

allocation are strategyproof. (Halpern et al. 2020; Babaioff, Ezra, and Feige 2021) both develop algorithms to compute such allocations. They further show that under binary valuations, and even submodular valuations, a truthful mechanism exists to compute EFX allocations.

Proportionality

One of the earliest notions of fairness it that of proportionality (PROP), where each good values their allocation at least html.frame. Clearly, like envy-freeness, it cannot be guaranteed int he case of discrete goods, so it is necessary to weaken it slightly by allowing the addition of goods. In proportionality up to 1 good (PROP1), there exists a good html.frame where html.frame. Similarly, in proportionality up to x (PROPx), all goods html.frame where html.frame.

(Conitzer, Freeman, and Shah 2017) showed that a PROP1 and PO allocation always exists and can be computed in polynomial time.

Still proportionality can be disappointing, as (Aziz, Moulin, and Sandomirskiy 2020) showed that even for simple cases, a PROPx allocation may not exist.

A PROPx allocation may not always exist.

Proof: Take 3 agents with identical valuations, and 5 goods. For all agents html.frame for html.frame and html.frame. No allocation admits a PROPx allocation. html.frame

An intermediary notion, PROPm has been shown to always exist and be computable in polynomial time. (Baklanov et al. 2021) defines the maximin good as html.frame is the largest among the smallest goods in other agent's bundles. If adding this good's value to html.frame's utility is greater than or equal to html.frame, i.e. html.frame, then an allocation is PROPm.

Fisher Markets

Although Nash Welfare is compelling, for its simultaneous EF1 + PO, it is also NP-hard to compute. One line of work attempting to simultaneous achieve fairness and efficiency tries to use the computation of market equilibria of fisher markets. This has also been used to compute approximate MNW, as mentioned previously. In the fisher market, goods are given prices html.frame, agents are given earnings html.frame, and monotone valuations, as defined above. These goods may be fractionally allocated with linear valuations, i.e. html.frame where html.frame is the fraction of html.frame given to html.frame.

A fisher market equilibrium is a fractional allocation in which

- 1. All goods html.frame allocated, i.e. that html.frame
- 2. For all agents html.frame
- 3. All agents only receive goods with maximum bang per buck, i.e. for all html.frame, if html.frame, then html.frame

When html.frame for all agents html.frame, this is called a Competitive Equilibrium for Equal Incomes (CEEI).

Although this remains an open question, prior work seeks to compute an approximate html.frame-CEEI allocation. In such an allocation, agents may spend html.frame for some html.frame.

Some work has been dedicated to computing approximations for CEEI. (Boodaghians, Chaudhury, and Mehta 2022) computes a html.frame-CEEI allocation with running time proportional to html.frame. (Chaudhury et al. 2022) gives an algorithm to compute a html.frame-CEEI in polynomial time for html.frame.

A fractionally Pareto optimal allocation (fPO) is a fractional allocation which is not Paretodominated by another fractional allocation. It is clear that an fPO allocation is PO, but not necessarily vice versa.

CEEI is compelling in computing fPO. (Mas-Colell, Whinston, and Green 1995) show that a CEEI is also fPO, and thus PO.

Empirical Results

We can see the practical usefulness of these results from prior experimental results. For discrete fair division, (Hosseini et al. 2023) collected a set of items, and computed an EF1 allocation among they agents. They then allowed agents to swap, and found that agents preferred to swap their bundles with other agents in html.frame of allocations.

Another common approach to allowing measurement of goods is to give each agent some number of "points", and allow them to distribute the points among the goods based on their preference, which for can still maintain the fairness properties of MNW and EF1. In Spliddit, for 1000 points and 10 agents, an MNW (EF1 and PO) allocation is computed in less than 3 seconds (Caragiannis et al. 2019; Dupuis-Roy and Gosselin 2009).

Discussion

In this survey, we discussed some of the most common notions of fairness. Although there are some further related notions of fairness, these are the most well-studied among the literature. We also showed that, under identical additive valuations, html.frame.

Related to fair division, within economics and computation (EC), recent research has also studied computing market equilibria, beyond the Fisher Market. Other works in EC focus more on strategyproofness, studying voting and consensus procedures.
